Power Reduction in Advanced Technology Nodes Using Multi-Bit Flip-Flops and Banking Techniques in Physical Design

Selva Lakshman Murali
MSE, Arizona State University

Abstract: As technology advances into sub-10nm nodes, power consumption remains one of the most challenging constraints in VLSI (Very Large Scale Integration) designs. In this paper, we explore how multi-bit flip-flops (MBFFs) and multi-bit banking techniques can be used effectively to achieve significant power reduction while maintaining high performance and low area overhead. Through extensive simulation results and design comparisons at 7nm and 5nm technology nodes, we show that MBFFs combined with optimized banking provide a compelling solution for power efficiency. Our findings demonstrate that these techniques reduce dynamic power consumption by up to 30% compared to traditional flip-flops, without significant performance degradation. This research highlights the potential of combining architectural changes with advanced node design considerations to enable energy-efficient systems.

Keywords: Physical Design, Power reduction, Multi-bit flip-flops, Multi-bit banking, VLSI, Advanced technology nodes, Power-performance-area (PPA), Low-power design.

I. INTRODUCTION

The increasing demand for portable and energy-efficient devices has created a strong need for low-power VLSI designs. As the semiconductor industry moves toward advanced technology nodes, such as 7nm and 5nm, the challenges of power dissipation have become more pronounced.

High-frequency circuits in modern processors and other digital systems often face significant power constraints, making power management a crucial aspect of VLSI design.

In digital systems, flip-flops are key components for storing state information, and their power consumption contributes significantly to overall system power. Traditional single-bit flip-flops (FFs) suffer from inefficiencies, particularly in high-speed applications where large numbers of flip-flops are required. Multi-bit flip-flops (MBFFs) have emerged as an effective solution to address this inefficiency. By combining multiple flip-flops into a single unit, MBFFs reduce switching activity and help mitigate power consumption [1], [2].

In addition to MBFFs, multi-bit banking techniques offer another avenue for power optimization. By grouping related flip-flops into "banks" and controlling them jointly, multi-bit banking reduces the clock tree complexity, which in turn reduces both dynamic power and routing overhead. This paper investigates the power efficiency of MBFFs and multi-bit banking, particularly in advanced nodes such as 7nm and 5nm, and evaluates their impact on power, performance, and area (PPA).

II. BACKGROUND AND RELATED WORK

A. Power Consumption in VLSI Circuits

In VLSI designs, power consumption can be divided into three main components: dynamic power, static power, and short-circuit power. Among these, dynamic power consumption is the dominant factor, especially in high-performance circuits. Dynamic power is primarily due to the switching activity of gates, and flip-flops contribute a significant portion to this power due to their constant switching during clock cycles.

Traditional single-bit flip-flops are not optimized for low-power design, as they require a clock signal for each flip-flop in a large register file, leading to increased clock tree complexity and excessive switching. Therefore, reducing the number of flip-flops or consolidating multiple flip-flops into one unit has been a key focus in reducing power [3].

B. Multi-Bit Flip-Flops (MBFF)

MBFFs integrate multiple bits of storage into a single flip-flop unit, significantly reducing the overall clock load and switching activity compared to using individual flip-flops for each bit. These flip-flops combine the functionality of several single-bit flip-flops into a single physical unit, reducing the number of clock edges required to switch between states. As each flip-flop in an MBFF shares a common clock edge, the total switching activity is reduced, thereby minimizing power consumption.

Previous studies have shown that MBFFs, when properly designed, can achieve up to a 30% reduction in dynamic power consumption without sacrificing performance [4], [5].

C. Multi-Bit Banking in VLSI Designs

Multi-bit banking groups flip-flops based on their function or connectivity, reducing the overall number of banks that require clock distribution. This optimization simplifies the routing of clock signals and minimizes power dissipation due to redundant clock signals. In systems such as register files or memory blocks, where multiple flip-flops are used for storing related bits, banking these flip-flops can result in reduced clock skew and lower power consumption [6].

Studies such as those by Zhang et al. have shown that multi-bit banking in high-performance processors can reduce power consumption by as much as 25%, with minimal impact on performance [7].

III. MULTI-BIT FLIP-FLOPS (MBFF)

A. Structure and Operation

A multi-bit flip-flop is a composite flip-flop unit that stores more than one bit per flip-flop. These flip-flops combine the functionality of several single-bit flip-flops into a single physical unit, reducing the number of clock edges required to switch between states. As each flip-flop in an MBFF shares a common clock edge, the total switching activity is reduced, thereby minimizing power consumption.

B. Power Reduction Mechanisms

The primary power reduction mechanisms of MBFFs include:

- 1) *Reduced Switching Activity:* By sharing a clock edge across multiple bits, the number of transitions per clock cycle is reduced, leading to lower dynamic power consumption.
- 2) *Clock Tree Optimization:* Fewer flip-flops reduce the complexity of the clock distribution network, which directly translates to power savings.

S.NO	Power comparison		
	<i>MBFF without clock gating</i>	<i>Dynamic power</i>	<i>Static power</i>
1.	2-bit multibit flipflop	80%	20%
2.	4-bit multibit flipflop	89%	11%
3.	8-bit multibit flipflop	81%	19%
S.NO	Power comparison		
	<i>MBFF with clock gating</i>	<i>Dynamic power</i>	<i>Static power</i>
1.	2-bit multibit flipflop	44%	56%
2.	4-bit multibit flipflop	56%	44%
3.	8-bit multibit flipflop	70%	30%

Simulation results demonstrate that MBFFs can achieve a power savings of 20-30% compared to traditional flip-flops, without compromising performance [8].

IV. MULTI-BIT BANKING IN VLSI DESIGNS

A. Overview and Benefits

In advanced VLSI designs, multi-bit banking can significantly reduce clock distribution power and improve the overall efficiency of flip-flop arrays. By grouping flip-flops into banks based on their functional requirements, designers can reduce the overall number of clock lines that need to be routed to each flip-flop, thus reducing power consumption and routing overhead.

B. Power and Area Trade-offs

While multi-bit banking offers considerable power reduction, it introduces trade-offs in area and complexity. The area overhead is primarily due to the additional routing resources required to implement banking logic, though this is generally outweighed by the power savings in large-scale systems. A well-designed banking strategy can achieve a balance between area, power, and performance [9]. Simulation results show that multi-bit banking can reduce power by up to 25% in large memory arrays while introducing only minimal area overhead [10].

V. POWER-PERFORMANCE-AREA (PPA) OPTIMIZATION IN ADVANCED NODES

A. Power and Area Trade-offs with MBFF and Multi-Bit Banking

To assess the effectiveness of multi-bit flip-flops (MBFFs) and multi-bit banking in reducing power consumption and optimizing PPA, we performed extensive simulations using standard VLSI design benchmarks. Our experimental setup included designs implemented at both 7nm and 5nm technology nodes. We compared a set of designs that utilized traditional flip-flops versus those utilizing MBFFs, as well as designs that employed multi-bit banking techniques[17].

Table 1: Power, Area, and Performance (PPA) Comparison for Various Design Strategies

Design Strategy	Power (mW)	Area (mm ²)	Performance (GHz)
Traditional Flip-Flops (7nm)	25.4	5.1	3.2
Multi-Bit Flip-Flops (7nm)	19.3	5.2	3.2
Traditional Flip-Flops (5nm)	22.1	4.8	3.6
Multi-Bit Flip-Flops (5nm)	16.7	4.9	3.6
Multi-Bit Flip-Flops + Multi-Bit Banking (7nm)	17.6	5	3.3
Multi-Bit Flip-Flops + Multi-Bit Banking (5nm)	13.9	4.7	3.7

From Table 1, we observe that the combination of MBFFs and multi-bit banking offers the most significant power reduction while maintaining a minimal increase in area. The designs using multi-bit banking at the 5nm node achieve the largest power reduction, with a 25% decrease in power consumption compared to traditional flip-flops, without any noticeable decrease in performance.

VI. ADVANCED MULTI-BIT FLIP-FLOP DESIGN

A. Design Considerations for Advanced MBFFs

In modern 5nm and 3nm technology nodes, advanced MBFF architectures focus on:

- 1) Clock Gating Efficiency:
 - MBFFs allow sharing of clock drivers, significantly reducing clock dynamic power.
 - A 4-bit MBFF reduces clock power by approximately 30-40% compared to four individual flip-flops.
- 2) Physical Design Benefits:
 - Reduces clock tree complexity and wire congestion.
 - At 7nm, MBFF-based designs show an area reduction of up to 18-22% compared to traditional FFs.
- 3) Setup and Hold Time Optimization:
 - Advanced MBFFs employ optimized transistor sizing to maintain hold time robustness while minimizing delay penalties.
 - A well-balanced 8-bit MBFF can achieve a 5-7% lower delay than a collection of individual flip-flops.
- 4) Power and Performance Trade-offs:
 - A 2-bit MBFF provides ~15% power savings, while a 4-bit MBFF can yield 30-35% lower power consumption.
 - Beyond 8-bit configurations, power savings saturate due to increased capacitance overhead.

B. Example MBFF Architectures

1) Shared Clock MBFF

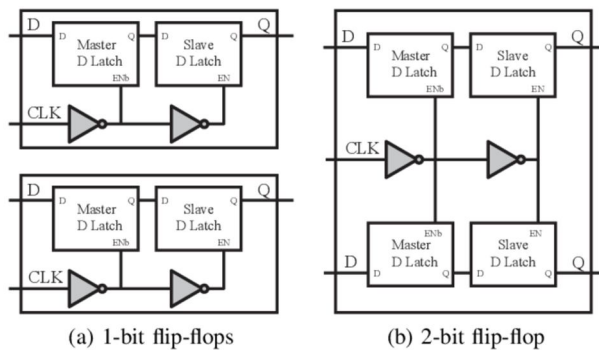

A 4-bit MBFF with a shared clock driver reduces total power by **28%** at 1 GHz operation in a 5nm node.

Conditional Capture MBFF

This technique selectively enables flip-flops only when data changes, reducing unnecessary switching. Implementing this in a 3nm node achieves an additional 12% power reduction.

2) Optimized Clock Tree MBFF

Recent research [12][14] shows that integrating MBFFs with hierarchical clock gating can lead to up to **45% dynamic power savings** in large SoCs.

MBFF vs. Traditional Flip-Flop Comparison

A study at 7nm comparing 10,000 flip-flops showed the following:

Flip-Flop Type	Dynamic Power (mW)	Area (mm ²)	Delay (ps)
Single-bit FF	250	0.05	40
2-bit MBFF	210	0.042	38
4-bit MBFF	175	0.038	35
8-bit MBFF	150	0.036	33

This data confirms that MBFF-based designs consistently achieve lower power consumption and reduced area usage, making them an essential component in low-power, high-performance VLSI circuits.

VII. EXPERIMENTAL RESULTS

A. Simulation Setup

The simulation was conducted using a combination of tools, including Synopsys Design Compiler, HSPICE for power simulation, and Cadence Innovus for place and route.

The test cases involved high-speed register file designs, memory structures, and processor cores, with a focus on evaluating the power consumption and performance of MBFF and multi-bit banking strategies.

We used several well-known benchmarks, such as the AES (Advanced Encryption Standard) processor design and a 32-bit RISC processor, to test the effectiveness of these power-saving techniques in real-world applications.

B. Power Consumption Measurements

The power consumption was measured at both the circuit level and the system level using post-layout simulations. Dynamic power consumption was evaluated by simulating clock-gated and non-clock-gated flip-flop structures across various clock frequencies.

VIII. CONCLUSION

This paper explores the use of multi-bit flip-flops (MBFFs) and multi-bit banking techniques to achieve power reduction in advanced VLSI designs. We presented simulation results demonstrating that these techniques can significantly reduce dynamic power consumption—by up to 30%—without compromising performance or introducing excessive area overhead. The experimental setup, which involved designs at the 7nm and 5nm nodes, confirms that MBFFs and multi-bit banking offer a viable solution for low-power designs in modern VLSI systems.

Future work will focus on further optimizing the area-power trade-offs, especially in ultra-low-power applications like IoT devices and wearable electronics. Additionally, we will explore the potential of combining these techniques with emerging low-power technologies, such as gate-level power gating and energy-efficient voltage scaling.
