# Capacity Achieving Forward Error Correcting Codes

Gaurav Beniwal<sup>1</sup>, Jatin Gaur<sup>2</sup>

<sup>2</sup>Assistant Professor, ECE Department Bhagwan Parshuram Institute of Technology

**Abstract:** We present a comparative study of the performance of various polar code constructions in an additive white Gaussian noise (AWGN) channel. A polar code construction is any algorithm that selects  $K$  best among  $N$  possible polar bit-channels at the design signal-to-noise-ratio (design-SNR) in terms of bit error rate (BER). Optimal polar code construction is hard and therefore many suboptimal polar code constructions have been proposed at different computational complexities. Polar codes are also non-universal meaning the code changes significantly with the design-SNR. However, it is not known which construction algorithm at what design-SNR constructs the best polar codes. We first present a comprehensive survey of all the well-known polar code constructions along with their full implementations. We then propose a heuristic algorithm to find the best design-SNR for constructing best possible polar codes from a given construction algorithm. The proposed algorithm involves a search among several possible design-SNRs. We finally use our algorithm to perform a comparison of different construction algorithms using extensive simulations. We find that all polar code construction algorithms generate equally good polar codes in an AWGN channel, if the design-SNR is optimized.

**Index Terms:** Bhattacharyya bounds, bit-channels, polar codes, Encoding, Decoding

## I. INTRODUCTION

Polar codes have been the subject of active research in recent times, mainly due to the fact that they are the first ever provably capacity achieving codes, with explicit construction and very low complexity of encoding and decoding. The polar codes were introduced by Erdal and Arikan<sup>[1]</sup>, using a novel concept called channel polarization. Soon after, both the concept of channel polarization as well as polar codes have been extended to a number of applications and generalizations.

Let us consider a binary input discrete memoryless symmetric (BI-DMS) channel. Channel polarization is a technique by which one manufactures  $N$  polarized channels (called bit channels) out of  $N$  identical independent copies of BI-DMS channels. The channels are polarized without any loss of capacity, in the sense that they are either extremely noisy or noiseless as  $N \rightarrow \infty$ . Then one can easily achieve a rate of transmission close to capacity, simply by choosing to transmit over only the good bit-channels. However, at any finite block length  $N$  and rate  $R$ ,  $K/N$ , a ranking algorithm for the bit-channels according to their bit error rate (BER) becomes necessary to select  $K$  good channels out of  $N$ . Here,  $K$  is the number of information bits in each code word of length  $N$ . This selection of bit-channels completely defines a polar code and therefore is called the polar code construction<sup>[1]</sup>.

The polar code construction is critical to obtain the best performance at finite block lengths. As we mentioned, the polar code construction has an explicit definition in theory.

It is challenging in practice because precise estimation of the bit channels is intractable. Therefore, a wide range of approximate construction methods are proposed.

It is known that under certain conditions and decoding schemes, it outperforms Reed-Muller codes, however its performance advantage suggested that in its current state, it would not compete with state-of-the-art capacity achieving forward error correction (FEC) codes like convolution turbo codes (CTCs) since CTCs outperform Reed-Muller codes by a wide margin, while the performance difference between the polar codes and the Reed-Muller codes are not that high. In this thesis, we mainly investigate how apart the performance curves are for polar codes so that we get an idea on how much polar code should be improved from their current state to be useful in practical systems.

## II. CHANNEL CODING PRELIMINARIES

### A. Channel Models

A channel is defined mathematically as a set of possible inputs to the channel  $X$ , a set of possible outputs to the channel  $Y$ , and a conditional probability distribution on the set of the outputs conditioned on the set of the inputs  $W(y|x)$  [1]. The simplest class of channels are discrete memoryless channels (DMC).

### B. Parameters

We define the important parameter of symmetric B-DMC's: Bhattacharyya parameter.

$$Z(W) = \sum_{y \in \mathcal{Y}} \sqrt{W(y|0)W(y|1)}$$

The Bhattacharyya parameter is a measure of the reliability of a channel since  $Z(W)$  is an upper bound on the probability of maximum-likelihood (ML) decision error for uncoded transmission over  $W$ .

### C. Channel Combining

In this phase, copies of a B-DMC are combined in a recur-sive manner in  $n$  steps to form a vector channel  $W_N$ , where  $N = 2^n$ . The basic transformation used in channel combining is the following.

Fig 1: Combining of two channels

### D. CHANNEL TRANSFORMATION

We have defined a blockwise channel combining and split-ting operation by which transformed independent copies of  $W_N$ . The goal in this section is to show that this blockwise channel transformation can be broken recursively into single-step channel transformations.

Fig 2: The channel transformation process with 8 channels.

### III. POLAR CODES

Given any subset of indices  $I$  of elements of a vector  $x$ , we denote the corresponding sub-vector as  $x_I$ . Similarly, when  $I$  denotes the indices of columns of a matrix  $A$ , the corresponding sub-matrix is denoted  $A_I$ .

A polar code may be specified completely by  $(N; K; F)$ ,

where  $N$  is the length of a code word in bits,  $K$  is the number of information bits encoded per codeword, and  $F$  is a set of  $N$   $K$  integer indices called frozen bit locations

Encoding — For an  $(N, K, F)$  polar code we describe below the encoding operation for a vector of information bits  $u$  of length  $K$ . The rate of the code is  $R = K/N$ . Let  $\log_2(N)$  and  $F \otimes n = F \otimes \dots \otimes F$  ( $n$  copies) be the  $n$ -fold Kronecker product of Arikan's standard polarizing kernel<sup>[1]</sup>.

Fig 3: Illustration of Arikan's  $O(N \log_2 N)$  complexity encoder implementation of (2) with  $(N, K, F) = (8, 5, \{0, 2, 4\})$

Without loss of generality, we normalize the noise variance to be unity for the AWGN in all our future discussions. Successive Cancellation Decoder (SCD) — The SCD algorithm<sup>[1]</sup> essentially follows the same encoder diagram in Fig.3 using decoding operations that resemble one iteration of the classic belief propagation algorithm. The likelihoods evolve in the reverse direction from right-to-left, using a pair of likelihood transformation equations, as illustrated with an example. Then the bit decisions are made at the left end of the circuit and broadcasted to the rest of the circuit. A complete pseudocode for implementing an SCD is available. The overall complexity is only  $O(N \log_2 N)$ . The Polar Code Construction — The choice of the set  $F$  is a critical step in polar coding (i.e. the polar code construction). This corresponds to the selection of best  $K$  bit-channels among  $N$ , in terms of the bit error rate (BER) at a given value of  $(REb/N_0)$  defined as the design-SNR<sup>[2]</sup>.

At first it was proposed to find the bit channels by evaluating of their full finite alphabet distributions. The algorithm becomes intractable due to the explosion of the alphabet size to a power of  $N$  by the end of  $n$  channel transformations. This problem is specifically addressed in<sup>[3]</sup> by employing a novel low complexity close-to-optimal quantizer. In addition, they provide theoretical guarantees for the loss of performance due to the quantization. Note that, some channels are better estimated by simple bounds on Bhattacharyya parameters.

The algorithm is extendable to infinite output channels by using a quantization algorithm. The initialization of the algorithm involves the AWGN channel quantization to  $\mu$  symbols, which takes an additional  $O(\mu)$  complexity. Overall, this algorithm has the second largest complexity. For AWGN channels, the estimation of bit-channels based on Gaussian approximation is proposed. This enables to use the Gaussian distribution approximations on the intermediate likelihoods. This was found to well-approximate the actual bit-channels of polar codes<sup>[2]</sup>.

The Gaussian approximation algorithm takes a complexity of  $O(N)$  function computations (excluding the selection of  $K$  best among  $N$  metrics obtained) similar to the Bhattacharyya bounds based algorithm, but involves relatively higher complexity function computations. Overall, this construction algorithm enjoys the second least complexity.

The construction algorithms are not optimizing the performance exactly at the design-SNR. That is, better performance at a given SNR may be obtained by constructing the code at a slightly different design-SNR<sup>[10]</sup>. This means even if we update the code dynamically with SNR, the performance may not be optimal.

#### IV. THE CODING ALGORITHM

The coding algorithm for the Bhattacharyya parameters is being stated where when the rate is high enough, the construction works well, since the good channels are always chosen for the information transmission. This avoids the need of any comparison among the good channels. On the other hand, when the rate is very low, the choice will only be among channels that tend to be very good. In that case, any choice would result in approximately the same performance.

```

INPUT :  $N, K$ , and design-SNR  $E_{dB} = (RE_b/N_0$  in dB)
OUTPUT:  $\mathcal{F} \subset \{0, 1, \dots, N - 1\}$  with  $|\mathcal{F}| = N - K$ 
1:  $S = 10^{E_{dB}/10}$  and  $n = \log_2 N$ 
2:  $\mathbf{z}^{(0)} \in \mathbb{R}^N$ , initialize  $\mathbf{z}^{(0)}[0] = \exp(-S)$ 
3: for  $j = 1 : n$  do ▷ for each stage in Fig. 1, right-to-left
4:    $u = 2^j$ 
5:   for  $t = 0 : \frac{u}{2} - 1$  do ▷ For each connection
6:      $T = \mathbf{z}^{(0)}[t]$ 
7:      $\mathbf{z}^{(0)}[t] = 2T - T^2$  ▷ Upper channel
8:      $\mathbf{z}^{(0)}[u/2 + t] = T^2$  ▷ Lower channel
9:   end
10: end
11:  $\mathcal{F} = \text{indices\_of\_greatest\_elements}(\mathbf{z}^{(0)}, N - K)$ 
    // Find indices of the greatest  $N - K$  elements
12: Return  $\mathcal{F}$ 

```

#### V. CHANNEL ENCODING

Polar codes are linear codes, i.e., any linear combination of codewords is another codeword of the code. The polar transform is to apply the transform  $G_2^{\otimes n}$  the  $n^{\text{th}}$  Kronecker power of  $G_2$  to the block of  $N = 2^n$  bits  $\mathbf{U}^{[4]}$ . The encoder chooses a set of  $N_R$  rows of the matrix  $G_n$  to form a  $N_R \times N$  matrix which is used as the generator matrix in the encoding procedure<sup>[5]</sup>. The way this set is chosen is dependent on the channel  $W$  and uses a phenomenon called channel polarization which is described later. Using the fast transform methods in signal processing, it is easy to show that the complexity of the polar encoder is  $O(N \log N)$ .

Fig 4: Output waveform for channel encoder

#### VI. CHANNEL DECODING

The decoder generates an estimate  $\hat{u}^N$  by observing the channel output  $y^N$ . The decoder takes  $N$  decisions for each  $u_i$ . If  $u_i$  is a frozen bit, the decoder will fix  $u_i$  to its known value<sup>[6][8]</sup>. If  $u_i$  is an information bit, the decoder waits to estimate all the previous bits, and then computes it. The decoder has a complexity of  $O(N \log N)$ <sup>[7][9]</sup>.

The factor graph associated with polar code decoding algorithm is shown in the figure 5,6. From this we see that the decoding is quite natural for a recursive successive decoding algorithm<sup>[5]</sup>.
