Study on Single Step Method for Synthesis of Nano Fluids

Kiran Kumar

Abstract: *This project primarily focuses and uses one-step chemical reduction method for synthesizing copper nanofluids by reducing copper sulfate by sodium hypophosphite using microwave irradiation. Thermal conductivity of the product obtained is measured and the variation of thermal conductivity with pH and concentration of precursor is studied. Stability of the dispersion formed is studied by measuring zeta potential at different pH values. One-step method for synthesizing nanofluids has been used to produce nickel nanofluids and properties of the product formed were studied by transmission electron microscopy and x-ray diffraction techniques. High energy ball milling was used to produce copper nanoparticles to be used in the two step method for synthesizing copper nanofluids. The effect of milling time on the size of the crystallites formed was studied.*

I. INTRODUCTION

In the development of energy-efficient heat transfer fluids, the thermal conductivity of the heat transfer fluids plays a vital role. Despite considerable previous research and development efforts on heat transfer enhancement, major improvements in cooling capabilities have been constrained because traditional heat transfer fluids used in today's thermal management systems, such as water, oils, and ethylene glycol, have inherently poor thermal conductivities, orders-of-magnitude smaller than those of most solids. Due to increasing global competition, a number of industries have a strong need to develop advanced heat transfer fluids with significantly higher thermal conductivities than are presently available. It is well known that at room temperature, metals in solid form have orders-of-magnitude higher thermal conductivities than those of fluids. For example, the thermal conductivity of copper at room temperature is about 700 times greater than that of water and about 3000 times greater than that of engine oil. The thermal conductivity of metallic liquids is much greater than that of nonmetallic liquids. Therefore, the thermal conductivities of fluids that contain suspended solid metallic particles could be expected to be significantly higher than those of conventional heat transfer fluids.

Modern nanotechnology can produce metallic or nonmetallic particles of nanometer dimensions. Nanomaterials have unique mechanical, optical, electrical, magnetic, and thermal properties. Nanofluids are engineered by suspending nanoparticles with average sizes below 100 nm in traditional heat transfer fluids such as water, oil, and ethylene glycol. A very small amount of guest nanoparticles, when dispersed uniformly and suspended stably in host fluids, can provide dramatic improvements in the thermal properties of host fluids. *Nanofluids* (*nanoparticle fluid* suspensions) is the term coined by Choi (1995) to describe this new class of nanotechnology-based heat transfer fluids that exhibit thermal properties superior to those of their host fluids or conventional particle fluid suspensions. *Nanofluid technology*, a new interdisciplinary field of great importance where nanoscience, nanotechnology, and thermal engineering meet, has developed largely over the past decade. The goal of nanofluids is to achieve the highest possible thermal properties at the smallest possible concentrations (preferably <1% by volume) by uniform dispersion and stable suspension of nanoparticles (preferably <10 nm) in host fluids. Maxwell's concept is old, but what is new and innovative in the concept of nanofluids is the idea that particle size is of primary importance.

A. Conventional Solid-Liquid Suspensions and Their Limitations

The century-old technique used to increase heat transfer rates is to disperse millimeter- or micrometer-sized particles in heat transfer fluids. The major problem with suspensions containing millimeter- or micrometer-sized particles is the rapid settling of these particles. If the fluid is kept circulating to prevent particle settling, millimeter- or micrometer-sized particles would wear out pipes, pumps, and bearings. Furthermore, such particles are not applicable to microsystems because they can clog microchannels. These conventional solid fluid suspensions are not practical because they require the addition of a large number of particles (usually, >10 vol%), resulting in significantly greater pressure drop and pumping power.

B. Potential applications

Electronics industry has provided computers with faster speeds, smaller sizes, and expanded features, leading to ever-increasing

International Journal for Research in Applied Science & Engineering Technology (IJRASET)

heat loads, heat fluxes, and localized hot spots at the chip and package levels. These thermal problems are also found in power electronics or optoelectronic devices. Air cooling is the most basic method for cooling electronic systems. However, heat fluxes over 100 W/cm² in electronic devices and systems will necessitate the use of liquid cooling.

In the transportation industry, cooling is a crucial issue because the trend toward higher engine power and exhaust-gas regulation or hybrid vehicles inevitably leads to larger radiators and increased frontal areas, resulting in additional aerodynamic drag and increased fuel consumption. A pressing need for cooling also exists in ultrahigh-heat-flux optical devices with brighter beams, such as high-powered x-rays.

II. EXPERIMENTAL WORK

A. Synthesis of Copper nanofluid

In the method proposed by Zhu et al (2004), Copper nanoparticles are produced by reducing copper sulfate with sodium hypophosphite. In a typical procedure, 25ml of ethylene glycol solution (0.1M) of copper sulfate penta hydrate is thoroughly mixed with 5ml of ethylene glycol solution (0.01M) of polyvinyl pyrrolidone (PVP-K30), using a magnetic stirrer for 30 min. Then 25ml of ethylene glycol solution of sodium hypophosphite (0.25M) is added and stirred for another 15min. The mixture is subjected to microwave heating till the reaction completes and the color of the mixture changes from blue to dark red. The obtained product is the copper-in- ethylene glycol nanofluid.

Chernogorenko V B and Tasybaeva Sh T proposed a mechanism for the reduction of copper sulfate with sodium hypophosphite. The metal ions are reduced by atomic hydrogen evolving from the reaction of hypophosphite with water.

In this case, the total reduction process may be written as:

However, it has been experimentally established that the reduction of M^{+2} cation corresponds to oxidation of two hypophosphite anions according to the equation :

Color changes during the course of the reaction indicate the formation of different complexes between copper sulfate and hypophosphite. As the copper sulfate solution is introduced into the hypophosphite solution, the blue copper sulfate solution becomes colorless (stage I), then turns green (stage II), and finally turns henna (stage III). The intermediate steps of the reduction mechanism for the synthesis are described as

follows. Stage I—formation of colorless copper(II) complex⁻ + 2H⁺

B. Characterization of the product

The product formed after the reaction is to be characterized and tested for the new phase formed. X-Ray Diffraction is used to verify whether the particles formed are of copper or not. High Resolution Transmission Electron Microscopy is used to find the size of the particles formed. Experimental details of the procedures of characterization are discussed below.

C. XRD Analysis

The nanofluid obtained is diluted with absolute ethanol, followed by centrifugation for 60 min at 4000 rpm, and then washed with ethylene glycol and then vacuum dried for 2hr at 80⁰C. The as-prepared powder samples are placed in the groove of the sample holder with the help of a glass slide. Then the sample holder is placed in an X-Ray Diffractometer (Philips PW 1710) in order to measure the diffraction pattern from its flattened surface. Diffraction pattern is obtained by projecting monochromatic Co-K α radiation of wavelength 1.79 Å⁰, filtered through a Fe-filter. Diffraction pattern consists of some peaks at particular points, characteristic of a material. So from the positions of peaks obtained, the phase formed is found out.

D. Tem analysis

Samples for the TEM analysis were prepared by diluting the nanofluids with ethylene glycol and subjecting the resulting dilute suspension to ultrasonic vibration for 1 hour. A drop of this sample was then placed on a carbon-coated ultra thin grid, which was used in TEM analysis. The micrographs were taken from selected regions of the specimen at different magnifications to resolve the size and morphology of particles and their distribution with help of a TEM microscope (JEOL/JEM- 2100). It has a provision

International Journal for Research in Applied Science & Engineering Technology (IJRASET)

of in- situ study of electron diffraction from selected area from the sample. Also, an elemental analysis was done to obtain the composition of the sample

E. Thermal conductivity of Copper nanofluid:

The thermal properties of the nanofluids are to be studied as they are supposed to be applicable as heat transfer fluids as a replacement for conventional fluids. Thermal conductivity is one of the important characteristics of heat transfer fluids.

F. Variation of thermal conductivity with

Copper nanofluid is prepared using 0.1M copper sulfate solution. The pH of the product is measured and the thermal conductivity values are measured by KD2 Thermal Properties Analyser, which employs transient hot wire-probe method, until consistent readings are observed. Then pH is varied by adding a little 3N NaOH solution to it and again thermal conductivity is measured. Thermal conductivity is measured at other pH values also by similarly varying the pH. The same procedure is carried out for the nanofluids obtained with 0.2M copper sulfate solution.

The variation of thermal conductivity with the change in the concentration of the precursor is also studied.

G. Thermal conductivity of reaction mixture and supernatant

After mixing the reactants – copper sulfate, sodium hypophosphite – and a small amount of dispersing agent, thermal conductivity is measured before microwave heating. Nanofluid is obtained by carrying out a reaction and after the product is formed, components other than copper are not removed. Any change in thermal conductivity can be due to the presence of these reaction components. To find out the effect of these materials present in the nanofluid formed, the nanofluid formed is centrifuged at 8000 rpm for 1hr to get the supernatant. Thermal conductivity of this supernatant is measured. Also, the pH of this supernatant is varied and thermal conductivity is measured as a function of pH.

H. Zeta Potential measurements

Due to dipolar characteristics and ionic attributes, the colloidal particles (including nanoparticles) suspended in solvents are charged electrically. For example, the surface groups of a colloid may be ionized. This leads to a net electric charge at the surface that causes the accumulation of opposite charges (counterions) around them. This in turn results in an electrical double layer. The ion (with positive or negative charge) and a set of counterions form a fixed part of the double layer. The diffuse or mobile part of the double layer consists of ions of different polarities, which extend into the liquid phase. This double layer may also be considered to have two parts, an inner region that includes ions bound relatively strongly to the surface, and a diffuse region in which the ion distribution is determined by a balance of electrostatic forces and random thermal motion. When an electric field is applied, the particles are attracted to the electrodes, depending on their polarity. The potential at which the fixed part of the double layer along with a part of the mobile layer move toward an electrode is called the *Zeta* or *electrokinetic potential*. It can also be defined as the potential at the shear plane of the particle when it moves in the medium.

Copper nanofluid is synthesized and samples with different pH values are prepared by using NaOH solution and each of them is analysed for zeta potential values using Zeta Sizer – Nano Series (Malvern Instruments). Samples were used as obtained and not

$$\beta_{hkl} = \frac{K\lambda}{L_{hkl} \cos \theta_{hkl}}$$

diluted.

I. Two-step method for Copper nanofluid

Mechanical alloying is employed to synthesize copper nanoparticles to produce nanofluid by dispersing them in ethylene glycol. 325-mesh sized copper particles were subjected to mechanical alloying at room temperature for 40 hours using a high energy ball mill at 250 rpm and 10:1 ball to powder weight ratio. Milling was carried out in wet condition, using toluene, to prevent undue oxidation, agglomeration of powders, changing the milling dynamics by smearing and coating the vials and ball surfaces with copper powder and ensuring sufficient output from the milling operation. Tungsten carbide balls of diameter 18mm were used for milling. The particle and grain sizes of the milled product were varied by milling up to different hours. Samples were collected at the end of 10hrs, 20 hrs, 30 hrs and 40 hrs of milling time by spreading the wet sample on to a butter paper and letting the toluene

International Journal for Research in Applied Science & Engineering Technology (IJRASET)

dry up where

β is the width of the peak at half maximum intensity of a specific phase (h k l) in radians

K is a constant that varies with the method of taking the breadth ($0.89 < K < 1$)

λ is the wavelength of incident x-rays

θ is the center angle of the peak

L is the crystallite length

Grain size is calculated for each sample using the width of peak at half the maximum intensity. This gives the effect of milling time on the particle size formed. The final product formed was dispersed in ethylene glycol and ultrasonicated intensely for 1 hr to produce 0.1 vol % copper in ethylene glycol nanofluid.

III. SYNTHESIS OF NICKEL NANOFLUID BY ONE-STEP METHOD

Thermodynamic analysis using the electrochemical potentials shows that the change in

Gibbs free energy (ΔG) for the net reduction reaction of nickel sulfate using sodium hypophosphite is negative i.e., the reduction of nickel sulfate using sodium hypophosphite is feasible. This point is used as the basis for extending the one step chemical reduction method to produce nickel nanofluid. The same procedure as used for the synthesis of copper nanofluid is used for the synthesis of nickel nanofluid also. 25ml of ethylene glycol solution (0.1M) of nickel sulfate heptahydrate is thoroughly mixed with 5ml of ethylene glycol solution (0.01M) of polyvinyl pyrrolidone (PVP-K30), using a magnetic stirrer for 30 min. Then 25ml of ethylene glycol solution of sodium hypophosphite (0.25M) is added and stirred for another 15min. The mixture is subjected to microwave heating till the reaction completes and the color of the mixture changes from green to black. The obtained product is nickel-in- ethylene glycol nanofluid.

The product formed is to be characterized by performing XRD and TEM analysis. The samples were prepared in the same procedure as was used to prepare samples from copper nanofluid. Diffraction pattern is obtained by projecting monochromatic Co-K α radiation of wavelength 1.79 Å, filtered through a Fe-filter.

IV. RESULTS & DISCUSSION

A. Copper nanofluid - Characterization

The diffraction patterns for all the samples prepared from copper nanofluid have the peaks in intensity at 2θ values of 50.8° , 59.35° , 88.85° with the peak at 50.8° being the highest. The inter-planar spacings (d-spacings) corresponding to these θ -values are 2.086Å , 1.809Å , 1.2786Å , calculated using Bragg's law ($\lambda = 2d \sin\theta$) with $\lambda = 1.79$

Å for Co K α radiation.

From the JCPDS file number 04-836, the peaks occur at 43° , 50° , 74° for pure copper, when the radiation used is Cu K α . The d-spacings corresponding to these θ -values are 2.088Å , 1.808Å , 1.278Å , calculated using Bragg's law ($\lambda = 2d \sin\theta$) with $\lambda = 1.5405$

Å for Cu K α radiation.

Thus, there is only a shift in the position of peaks due to change in the radiation; but essentially, the peaks are occurring at the same d-spacing. Hence, it can be confirmed that the dispersion formed by the reaction has the copper particles as the dispersed phase.

Fig 4.1.1 (a)

Fig 4.1.1: X-Ray Diffractograms of samples prepared using 0.1M and 0.2M CuSO₄ solutions, corresponding to (a) and (b) respectively.

Fig 4.1.2

Fig 4.1.2.(b)

Fig 4.1.2.(c)

Fig 4.1.2: TEM micrographs of samples prepared from 0.1M, 0.2M, 0.3M CuSO₄ corresponding to (a),(b),(c) respectively

From the micrographs, the size of particles is uniform in all the cases. Uniformity in the size of the particles can be attributed to the microwave irradiation because it avoids the temperature and concentration gradients which in turn leads to uniform and rapid

International Journal for Research in Applied Science & Engineering Technology (IJRASET)

nucleation and restricts the straightforward growth of newly born Cu. The size of the particles formed increased along with the increase in the concentration of precursor. This is due to the fact that, the nuclei formed have enough time to grow while the rest of the reactant is being consumed. Size of most of the particles is less than 20nm and some others are in the range of 20-50 nm. Elemental analysis was also performed along with transmission electron microscopy. The results show that all the three samples have only copper along with a small amount of carbon. Carbon actually is from the carbon-coated ultra-thin grid that is used to hold the sample in TEM.

B. Thermal conductivity enhancement in copper nanofluid

The thermal conductivity of the nanofluids are higher than that of the base fluid, ethylene glycol ($k=0.253 \text{ Wm}^{-1} \text{ }^{\circ}\text{C}^{-1}$). It was observed that as the concentration of the precursor is increased, the effective thermal conductivity of the suspension also increased. The enhancements were as high as 5.14 %, 12.24% and 15.23% for the nanofluids prepared from 0.1M, 0.2M, 0.3M CuSO_4 solutions respectively.

C. Effect of pH on thermal conductivity

Thermal conductivity of the nanofluids prepared from 0.1M and 0.2M CuSO_4 were studied by varying the pH of the suspensions. It was observed that as the pH of the suspension increased, the effective thermal conductivity also increased in both the cases. This is because of the fact that, varying pH has a direct effect on the dispersion quality of a suspension. Better the quality of dispersion, higher is the effective thermal conductivity.

D. Increase in thermal conductivity was as high as 16%, at a pH of 13, for the nanofluid prepared from 0.1M CuSO_4 solution and for that prepared from 0.2M solution, it was 19.57% at a pH of 11.3.

E. Thermal conductivity of reaction mixture and supernatant

The thermal conductivity of the reaction mixture before microwave heating was measured to be $0.2553 \text{ W/m}^{\circ}\text{C}$. Thus, the thermal conductivity enhancement with respect to the base fluid recorded was 0.2%, which is a negligible quantity. Supernatant obtained after centrifuging the nanofluid has no solid particles present in it. The thermal conductivity of this supernatant was measured to be $0.255 \text{ W/m}^{\circ}\text{C}$. Thus, the thermal conductivity enhancement with respect to the base fluid recorded was 0.2%, which is also a negligible quantity. With the nanoparticles present, the nanofluid recorded an enhancement of 5.14%, which is a significant figure. Thus the effect of the reaction components present in the nanofluid can be neglected and the enhancement in thermal conductivity must be due to the presence of copper nanoparticles only. Also, when the pH of supernatant was varied, no change was observed in the value of thermal conductivity. Thus the increase in thermal conductivity of the nanofluid with the increase in pH can be said to be due to the effect of OH^- ions (added to the nanofluid) on the nanoparticles.

F. Zeta potential measurements

Zeta potential is measured to study the stability of the dispersion formed due to the reaction. The zeta potential values of the samples of different pH values did not follow any particular trend. All the values are not in the desirable range (absolute values are less than 20 mV). This may be because the dispersion formed is highly unstable. Another point that can be a reason for this abnormality may be high particle density that the samples used for measurement had.

Fig. 4.2.2. Variation of Zeta Potential with pH

International Journal for Research in Applied Science & Engineering Technology (IJRASET)

G. Two step method for copper nanofluid

The samples collected after 10 hr, 20 hr, 30 hr and 40 hr of milling are collected and are subjected to X-Ray diffraction analysis. Diffraction pattern is obtained by projecting monochromatic Co-K α radiation of wavelength 1.79 Å, filtered through a Fe-filter. Peaks obtained were observed to be of pure copper for all the samples and the peak widths are to be used to calculate the grain size of the crystal.

The grain size formed from milling is calculated using Scherrer formula given below:

Where

$$\beta_{hkl} = \frac{K\lambda}{L_{hkl} \cos \theta_{hkl}}$$

β is the width of the peak at half maximum intensity of a specific phase (h k l) in radians

K is a constant that varies with the method of taking the breadth ($0.89 < K < 1$)

λ is the wavelength of incident x-rays, θ is the center angle of the peak

Grain sizes obtained from the highest peaks in the patterns of the four samples are 81 nm, 64 nm, 51 nm and 36 nm. It may be noted that the actual particle size will be higher than the grain size obtained for each sample. Milling the final sample obtained further may

International Journal for Research in Applied Science & Engineering Technology (IJRASET)

even decrease the grain size.

Fig. 4.5.1. XRD pattern of the sample prepared from the product obtained from NiSO₄ solution

H. Nickel nanofluid - Characterization

Similar to the XRD patterns of copper nanoparticles, there is a shift in the position of peaks due to change in the radiation. The diffraction patterns of the sample prepared from nickel nanofluid have the peaks in intensity at 2θ values of 52.14° , 60.9° , 90° with the peak at 52.14° being the highest. The inter-planar spacings (d-spacings) corresponding to these θ -values are 2.036 \AA , 1.76 \AA , 1.24 \AA , calculated using Bragg's law ($\lambda = 2d \sin\theta$) with $\lambda = 1.79\text{ \AA}$ for Co $K\alpha$ radiation.

For pure face-centered nickel, the peaks occur at 44.5° , 51.8° , 76.4° , when the radiation used is Cu $K\alpha$. The d-spacings corresponding to these θ -values are 2.036 \AA , 1.765 \AA , 1.247 \AA , calculated using Bragg's law ($\lambda = 2d \sin\theta$) with $\lambda = 1.5405\text{ \AA}$ for Cu $K\alpha$ radiation. Hence, it can be confirmed that the dispersion formed by the reaction has the nickel particles as the dispersed phase

Fig. 4.5.2. TEM micrographs of product obtained from NiSO₄ solution

V. CONCLUSIONS

Nanofluids synthesized by a single step chemical reduction method have particles of very small and uniform size. Thermal

International Journal for Research in Applied Science & Engineering Technology (IJRASET)

conductivity of nanofluid is higher than that of the base fluid (ethylene glycol in this work). Enhancement in thermal conductivity is due to the presence of nanoparticles and the effect of the presence of other components in the dispersion is negligible. As the concentration of the precursor increases i.e., as the volume fraction of the copper particles increases, the thermal conductivity also increased. Also, as the pH of the nanofluid is increased, the thermal conductivity of the nanofluids increased. Zeta potential, used as a parameter to estimate the stability of the suspension, did not fall in the desirable range. The one-step method used previously for copper nanofluids is extended to nickel nanofluids using the same reducing agent. Two-step method for preparing copper nanofluids was also employed.

VI. FUTURE WORK

The stability of the nanofluids is to be studied more comprehensively.

The effect of the type of dispersing agent (organic/polymer etc) on the properties of the nanofluids is to be studied.

The nanofluid prepared by this one-step method is to be applied to a heat transfer system to find out the enhancement in the heat transfer rates.

VII. ACKNOWLEDGMENT

This project completion gives us immense pleasure .we would like to convey our sincere gratitude to A.Subbarao Professor of ChemicalDepartment . We would also expand our deepest gratitude to all those who has directly and Indirectly guided us in writing this thesis .
